## ABSTRACT

Unlike the well-studied problem of Quantum State Discrimination (QSD), which aims to identify an unknown quantum state from a known ensemble, Quantum State Exclusion (QSE) focuses on confidently ruling out one or more possible candidates. This approach becomes particularly valuable in scenarios where exclusion can be achieved without error.

This project investigates QSE under two principal protocols, Minimum Error (ME), which aims to minimize the risk of incorrectly excluding the true state, and Zero Error (ZE), which seeks to guarantee perfect exclusion at the cost of potentially inconclusive outcomes. Building on recent analytical results for group generated ensembles in these protocols [1], we carry out a numerical study of QSE task using Semidefinite Program (SDP) techniques, analyzing general ensembles and benchmarking them against the group generated cases, i.e. the lower bound.

We begin by introducing the mathematical formulation of the QSE problem and the theoretical tools necessary to interpret our results. We also describe a protocol for generating random generic ensembles in a homogeneous manner according to the Haar measure.

Our findings confirm that the analytical bounds established for group generated ensembles serve as effective lower bounds for more general cases. We present detailed results for three-state ensembles and examine the statistical distribution of correct exclusion probabilities for randomly sampled ensembles. Furthermore, we provide theoretical insights and intuition to support the observed behavior.

These results underscore the unique role of QSE in quantum information theory, particularly in contexts where partial state inference and hypothesis elimination are more feasible or desirable than full state identification.

## 1 INTRODUCTION

In many real-world scenarios, excluding a certain hypothesis can be more practical than solving the problem entirely. For instance, in disease diagnosis, ruling out potential illnesses is often the first step toward identifying the actual condition. Similarly, in the context of detecting a gas leak in a complex pipe system, excluding the possibility of the gas being chlorine, a toxic substance, can guide the search for the faulty pipe by narrowing down the potential sources and providing critical information about the gas's toxicity. In numerous everyday situations, the strategy of excluding specific possibilities forms a natural and often effective initial approach to the problem.

In the quantum realm, a similar line of reasoning can be applied in some tasks in this field. One of the fundamental tasks in quantum information theory is the identification of an unknown quantum state known to belong to a given ensemble of possible states. This task is referred to as Quantum State Discrimination (QSD), and it has been extensively studied in the literature [2]. However, instead of aiming to identify the exact state, we may take another approach by applying the hypothesis exclusion idea. That is, given a quantum state known to be one among a certain ensemble, the goal becomes to rule out the possibility of the unknown state being a specific member of that ensemble. This alternative task is known as Quantum State Exclusion (QSE) [3], and it offers a distinct framework with its own set of advantages [4] with respect to its counterpart QSD.

We can approach QSE task under several protocols, depending on the context within we perform the hypothesis exclusion we can prefer one or another. In this project, we focus on two main protocols, Minimum Error (ME) and Zero Error (ZE)<sup>1</sup>, i.e. the protocols for which analytical results have been presented [1]. In the ME scenario, the goal is to minimize the probability of mistakenly excluding the actual prepared state. In contrast, the ZE approach seeks to exclude a state with absolute certainty, although this procedure sometimes yields an inconclusive result when perfect exclusion cannot be accomplished.

While QSD has seen significant progress over the years [5, 6], QSE has remained relatively underexplored until recently. New analytical results have emerged [1] for both the ME and ZE protocols. In particular, when the ensemble is generated through the action of a finite algebraic group, the problem becomes more tractable, highlighting QSE as a worthwhile object of study.

Although the tasks of exclusion and discrimination coincide for ensembles containing only two states<sup>2</sup>, when dealing with ensembles of three or more states, the two problems diverge in both approach and complexity. In order to further motivate the interest in QSE and discuss the main differences, we include a brief comparison of both tasks and protocols with QSD in Appendix C. One of the key features of QSE is the possibility of achieving *perfect exclusion*,

---

<sup>1</sup>Also known as *unambiguous exclusion*.

<sup>2</sup>Since for the two states case excluding one necessarily implies identifying the other.

i.e. confidently ruling out a candidate state with complete certainty that it is different from our given unknown state. In contrast, *perfect discrimination* is generally not achievable, meaning that one cannot identify the unknown state with absolute certainty in most settings[7].

This capacity for perfect exclusion opens new avenues in quantum information theory, especially in scenarios involving partial information retrieval from quantum systems [8]. By eliminating certain hypotheses, one can extract meaningful information from a quantum system without requiring full state identification.

Building upon the recent results for the probability of a correct exclusion for group generated ensembles [1],<sup>3</sup> this project undertakes a numerical investigation into QSE, highlighting the analytical results from group generated ensembles as lower bounds for more general cases. The project commences with a preliminaries section that outlines the mathematical framework underlying the QSE task, along with the essential tools used in our analysis. We then present results for the probability of correct hypothesis exclusion in ensembles consisting of three quantum states, the simplest case. Furthermore, we explore the distribution of correct exclusion probabilities for randomly generated ensembles sampled according to Haar measure.<sup>4</sup>

To carry out our numerical analysis, we employ SDP techniques,[9] which enable us to formulate the QSE task as a convex optimization problem. The SDP approach has proven particularly effective for problems of this nature [10]. Finally, we conclude by providing some theoretical intuition and insights based on our results.

---

<sup>3</sup>A proper definition of a *group generated ensemble* will be given in the *Group generated ensembles* section 2.4, for the time being, we can identify them as ensembles that comprehend set of states that exhibit a certain symmetry.

<sup>4</sup>The importance of the generic ensembles generation being performed according to Haar measure is a key for the numerical analysis and it is discussed in the *Methodology* section (3)

## 2 PRELIMINARIES

In this section we introduce some mathematical formalism of the postulates of Quantum Mechanics as well as some relevant objects in order to introduce the mathematical framework of QSE in a SDP form. Additionally we define the Haar measure and discuss its importance for a proper generation of generic ensembles.

### 2.1 POSTULATES AND DEFINITIONS

This project is entirely situated within the quantum realm. Therefore, we begin by contextualizing the foundational postulates, notation, and elements upon which the rest of the project relies on.

**Postulate I:** A quantum state provides a complete description of a physical system. In quantum mechanics, a state can be represented by a normalized vector  $|\psi\rangle$  in a Hilbert space  $\mathcal{H}$ . Hence, each physical system corresponds to a unique Hilbert space.

**Postulate II:** An observable  $O$  is a measurable property of a physical system. Mathematically, observables are represented by hermitian operators.

**Postulate III:** The eigenvalues  $o_i$  of a hermitian operator  $O = \sum_i o_i P_i$  represent the possible outcomes of measuring the observable  $O$ . Upon measuring  $O$  and obtaining the result  $o_i$ , the quantum state  $|\psi\rangle$  collapses to the state

$$\frac{P_i |\psi\rangle}{\sqrt{p_i}},$$

where  $P_i$  is the projector onto the eigenspace associated with the eigenvalue  $o_i$ , and  $p_i = \|P_i |\psi\rangle\|^2$  is the normalization factor.

**Postulate IV:** The probability  $p_i$  of obtaining outcome  $o_i$  when measuring the observable  $O = \sum_i o_i P_i$  on a system described by the quantum state  $|\psi\rangle$  is given by

$$p_i = \text{Tr}(P_i |\psi\rangle \langle \psi|) = \|P_i |\psi\rangle\|^2 = \langle \psi | P_i | \psi \rangle.$$

In relation to Postulate I, it is often convenient to represent quantum states using the *density matrix* formalism, where a pure state is described by  $\rho = |\psi\rangle \langle \psi|$  instead of  $|\psi\rangle$ .

Using this representation, Postulates III and IV are reformulated. The post-measurement state has a density matrix

$$\frac{P_i \rho P_i}{p_i},$$

and the probability of obtaining outcome  $o_i$  is

$$p_i = \text{Tr}(P_i \rho).$$

Both formulations are equivalent, though one may be more convenient than the other depending on the context. Furthermore, the density matrix formalism naturally introduces the concept of *mixed states*. Until now, we have implicitly dealt only with *pure states*, i.e., states of the form  $\rho = |\psi\rangle\langle\psi|$ . Suppose now that, for reasons we ignore, the system is prepared in one of several pure states  $\{\rho_i\}_{i=1}^n$  with probabilities  $\{\eta_i\}_{i=1}^n$ . Then the overall state of the system is described by the mixed state

$$\rho = \sum_{i=1}^n \eta_i \rho_i.$$

For the purposes of this project, we focus exclusively on pure states and do not address scenarios involving mixed states.

In relation to the observable postulate, we now define a Positive Operator-Valued Measure (POVM) as a collection of measurement operators  $\{\Pi_i\}_{i=1}^n$  that satisfy,

- Each  $\Pi_i$  is positive semi-definite hermitian operator, meaning all its eigenvalues  $\pi_j^{(i)}$  satisfy  $\pi_j^{(i)} \geq 0$ .
- The operators satisfy the completeness relation,

$$\sum_{i=1}^n \Pi_i = \mathbb{1},$$

where  $\mathbb{1}$  denotes the identity operator on the Hilbert space  $\mathcal{H}$ .

Unlike projective measurements, the operators  $\Pi_i$  in a POVM are not necessarily orthogonal projectors. This allows the number of measurement outcomes to exceed the dimensionality of the Hilbert space, extending the previous orthogonal measurement to a more generic status and making POVMs particularly useful in tasks such as QSE and QSD.

## 2.2 FORMULATION OF THE PROBLEM

Let  $\{(\rho_i, \eta_i)\}_{i=1}^n$  be an ensemble of  $n$  quantum states, where each  $\rho_i$  denotes a pure state density matrix<sup>5</sup>, i.e.,  $\rho_i = |\psi_i\rangle\langle\psi_i|$ , and  $\eta_i$  represents the prior probability of occurrence of the state  $\rho_i$ . Let  $\tilde{\rho}$  be a state from this ensemble. Our objective is to develop a procedure to identify another state  $\rho_j \in \{\rho_i\}_{i=1}^n$ , such that  $\rho_j \neq \tilde{\rho}$ .

Additionally, let  $\{\Pi_i\}_{i=1}^n$  be a set of POVMs acting on the Hilbert space  $\mathcal{H}$  of the quantum system. Here we present the two studied protocols for QSE: Minimum Error (ME) and Zero Error (ZE).

As previously discussed the goal of the ME protocol is to minimize the probability of incorrectly excluding the unknown state from our hypothesis. If we formulate the error probability

---

<sup>5</sup>This formulation holds true for mixed states but the project will only consider the pure state scenario.

as an SDP, we obtain,<sup>6</sup>

$$\begin{aligned} P_{\text{ME}}^e &= \min_{\{\Pi_i\}} \sum_{i=1}^n \eta_i \text{Tr}(\Pi_i \rho_i), \\ \text{subject to } & \sum_{i=1}^n \Pi_i = \mathbb{1}, \quad \Pi_i \geq 0 \quad \forall i \in \{1, \dots, n\}. \end{aligned}$$

Note the constraints  $\sum_{i=1}^n \Pi_i = \mathbb{1}$  and  $\Pi_i \geq 0$  ensure that the set  $\{\Pi_i\}_{i=1}^n$  form a valid POVM, raising a proper probability distribution. The superscript  $e$  in  $P_{\text{ME}}^e$  indicates that this is the *error probability*.

Alternatively, we may formulate the problem in terms of the *success probability*, denoted by  $P_{\text{ME}}^s$ , which quantifies the probability of a correct exclusion. This equivalent formulation reads,

$$\begin{aligned} P_{\text{ME}}^s &= \max_{\{\Pi_i\}} \left( 1 - \sum_{i=1}^n \eta_i \text{Tr}(\Pi_i \rho_i) \right), \\ \text{subject to } & \sum_{i=1}^n \Pi_i = \mathbb{1}, \quad \Pi_i \geq 0 \quad \forall i \in \{1, \dots, n\}. \end{aligned}$$

Naturally, both formulations are related via,

$$P_{\text{ME}}^s + P_{\text{ME}}^e = 1.$$

In the case of the ZE protocol, the objective is to exclude with total certainty a state known to be different from the unknown state. However, the protocol might lead to inconclusive result. In order to do so, the POVMs must also satisfy an unambiguity condition, i.e. each measurement operator  $\Pi_i$  must be orthogonal to the corresponding state  $\rho_i$ . In other words,

$$\text{Tr}(\Pi_i \rho_i) = 0 \quad \forall i \in \{1, \dots, n\}.$$

To ensure completeness, we introduce an additional POVM element  $\Pi_?$  representing an inconclusive result,

$$\Pi_? = \mathbb{1} - \sum_{i=1}^n \Pi_i.$$

If the measurement yields the outcome "?" , the result is inconclusive.

---

<sup>6</sup>Note that SDP formulations for quantum state discrimination may differ from exclusion tasks by interchanging minimization and maximization objectives.

The corresponding SDP for minimizing the probability of an inconclusive result, i.e. error, in the ZE protocol is,

$$\begin{aligned} P_{\text{ZE}}^e &= \min_{\{\Pi_i\}} \sum_{i=1}^n \eta_i \text{Tr}(\Pi_i \rho_i), \\ \text{subject to } & \sum_{i=1}^n \Pi_i + \Pi_? = \mathbb{1}, \quad \Pi_? \geq 0, \\ & \text{Tr}(\Pi_i \rho_i) = 0, \quad \Pi_i \geq 0 \quad \forall i. \end{aligned}$$

The corresponding success probability is naturally given by, the maximization of  $1 - P_{\text{ZE}}^e$  under the same constraints.

Notice this formulation is analogous to the ME protocol, with the crucial difference being the constraint  $\text{Tr}(\Pi_i \rho_i) = 0$ , enforcing unambiguous discrimination.

Additionally, in some cases it is useful to consider the dual formulation of the problem, as solving the dual version of the SDP can often be more computationally efficient. Moreover, one may consider an ansatz, i.e. a candidate set of POVMs, and compute the exclusion success probability under a given protocol. This provides a lower bound for the success probability, since in principle we cannot guarantee that this ansatz is optimal, i.e. there may exist another set of POVMs yielding a higher success rate.

However, by evaluating the same set of POVMs within the dual formulation, we can obtain an upper bound on the success probability. If the upper and lower bounds coincide, we can conclude that the chosen POVM set is indeed optimal. For this reason, we present the dual formulation of the problem in Appendix A. This procedure is standard for verifying the optimality of a given POVM set and closely resembles the internal computations performed by a SDP solver.

### 2.3 GRAM MATRIX FORMULATION

The Gram matrix formulation recasts the SDP problems associated with the exclusion task in a more basis-independent manner. This approach reveals that the exclusion tasks for certain ensembles can be equivalent to those of others. As such, we adopt this formulation in our analysis, as it offers valuable insight into the underlying relationships between the quantum states in the ensemble.

Given an ensemble  $\{(\rho_i, \eta_i)\}_{i=1}^n$  of  $n$  quantum states we define the  $\mathcal{G} \in \mathbb{C}^{n \times n}$  be the *Gram matrix* of the ensemble, as the  $n \times n$  positive semidefinite Hermitian matrix given by,

$$\mathcal{G} = \begin{pmatrix} \eta_1 & \sqrt{\eta_1 \eta_2} \langle \psi_1 | \psi_2 \rangle & \dots & \sqrt{\eta_1 \eta_n} \langle \psi_1 | \psi_n \rangle \\ \sqrt{\eta_2 \eta_1} \langle \psi_2 | \psi_1 \rangle & \eta_2 & \dots & \sqrt{\eta_2 \eta_n} \langle \psi_2 | \psi_n \rangle \\ \vdots & \vdots & \ddots & \vdots \\ \sqrt{\eta_n \eta_1} \langle \psi_n | \psi_1 \rangle & \sqrt{\eta_n \eta_2} \langle \psi_n | \psi_2 \rangle & \dots & \eta_n \end{pmatrix},$$

that is,  $\mathcal{G}_{i,j} = \sqrt{\eta_i \eta_j} \langle \psi_i | \psi_j \rangle$ . Since all states are normalized, the diagonal elements are equal to  $\eta_i$ .

By construction, the Gram matrix is Hermitian,

$$\mathcal{G}_{i,j}^* = (\sqrt{\eta_i \eta_j} \langle \psi_i | \psi_j \rangle)^* = \sqrt{\eta_j \eta_i} \langle \psi_j | \psi_i \rangle = \mathcal{G}_{j,i}.$$

Additionally,  $\mathcal{G}$  is positive semidefinite. To see this, consider an arbitrary state  $|\Phi\rangle$  and an orthonormal basis  $\{|i\rangle\}_{i=1}^n$ , then,

$$\begin{aligned} \langle \Phi | \mathcal{G} | \Phi \rangle &= \langle \Phi | \left( \sum_{i,j=1}^n \sqrt{\eta_i \eta_j} \langle \psi_i | \psi_j \rangle |i\rangle \langle j| \right) | \Phi \rangle \\ &= \sum_{i,j=1}^n \sqrt{\eta_i \eta_j} \langle \psi_i | \psi_j \rangle \langle \Phi | i \rangle \langle j | \Phi \rangle \\ &= \left\| \sum_{i=1}^n \eta_i \langle i | \Phi \rangle | \psi_i \rangle \right\|^2 \\ &\geq 0. \end{aligned}$$

Since  $\mathcal{G}$  is Hermitian and positive semidefinite, it can be factorized as,

$$\mathcal{G} = X^\dagger X,$$

for some matrix  $X$ , whose columns are the pure states,

$$X = \begin{pmatrix} & & & \\ \sqrt{\eta_1} |\psi_1\rangle & \sqrt{\eta_2} |\psi_2\rangle & \dots & \sqrt{\eta_n} |\psi_n\rangle \\ & & & \end{pmatrix}.$$

Let us fix an arbitrary orthonormal basis  $\{|\omega_i\rangle\}_{i=1}^n$ . Then, the diagonal entries of  $X$  in this basis are given by,

$$X_{i,i} = \sqrt{\eta_i} \langle \omega_i | \psi_i \rangle.$$

<sup>7</sup>We define the POVM elements as projectors  $\Pi_i = |\omega_i\rangle \langle \omega_i|$ . Then, for the ensemble  $\{(\rho_i, \eta_i)\}_{i=1}^n$ , the corresponding semidefinite program (SDP) constraints become,

$$\begin{aligned} \eta_i \text{Tr}(\Pi_i \rho_i) &= \eta_i \text{Tr}(|\omega_i\rangle \langle \omega_i| |\psi_i\rangle \langle \psi_i|) \\ &= |\sqrt{\eta_i} \langle \omega_i | \psi_i \rangle|^2 \\ &= |X_{i,i}|^2. \end{aligned}$$

---

<sup>7</sup>Note that fixing the basis  $\{|\omega_i\rangle\}_{i=1}^n$  uniquely determines the decomposition  $\mathcal{G} = X^\dagger X$ , and vice versa.

Thus, we can reformulate the SDP for the minimum-error (ME) protocol as,

$$\begin{aligned} P_{ME}^e &= \min_X \sum_{i=1}^n |X_{i,i}|^2, \\ \text{subject to } X^\dagger X &= \mathcal{G}, \quad X \geq 0. \end{aligned}$$

Similarly, the success probability becomes,

$$\begin{aligned} P_{ME}^s &= \max_X \left( 1 - \sum_{i=1}^n |X_{i,i}|^2 \right), \\ \text{subject to } X^\dagger X &= \mathcal{G}, \quad X \geq 0. \end{aligned}$$

This reformulation reveals that if two ensembles  $A$  and  $B$  share the same Gram matrix, then their exclusion problems under both the ME and ZE protocols are equivalent. That is, their optimal success and error probabilities coincide. Consequently, we focus on the Gram matrix to study exclusion problems rather than the explicit state representations, as it encodes all the relevant information.

## 2.4 GROUP GENERATED ENSEMBLES

As we have mentioned before (Section 1), analytical results have been found for the exclusion task in both protocols ME and ZE for ensembles that exhibit a certain degree of symmetry[1], that is for *group generated* ensembles. In this section we present a proper definition for a group generated ensemble as well as a brief discussion on this ensembles generated by a cyclic group, a key type of group generated ensembles in our analysis.

Given a quantum state  $|\psi\rangle$ , referred to as the *seed state*, we define a *group generated ensemble* as the set of states obtained by applying a group of unitary transformations to  $|\psi\rangle$ . Specifically, if the ensemble consists of  $n$  quantum states, its elements are of the form,

$$U_i |\psi\rangle, \quad i \in \{1, \dots, n\},$$

where the set of unitary matrices  $\{U_i\}_{i=1}^n$  forms a finite group under standard matrix multiplication. In terms of density matrices, the ensemble can equivalently be written as,

$$\rho_i = U_i \rho U_i^\dagger, \quad i \in \{1, \dots, n\},$$

where  $\rho = |\psi\rangle \langle \psi|$  is the density matrix corresponding to the seed state.

For instance, let  $\mathcal{U}$  be a unitary operator such that  $\mathcal{U}^n = \mathbb{1}$  (i.e.,  $\mathcal{U}$  generates a cyclic group of order  $n$ ). Then, the set of states

$$\{\mathcal{U}^i |\psi\rangle\}_{i=0}^{n-1},$$

forms a group generated ensemble based on the cyclic group  $\mathbb{Z}/n\mathbb{Z}$ . This type of ensemble is of particular interest in our study and will be explored in more detail at the end of this section. Nonetheless, in Appendix B we present a general procedure to compute the Gram Matrix for any group generated ensemble.

### The $\mathbb{Z}/n\mathbb{Z}$ group generated ensemble

Here we discuss the particular case for a  $\mathbb{Z}/n\mathbb{Z}$  group generated ensemble a key type of ensemble for our project.<sup>8</sup> Let  $\mathcal{U} \in U(n)$  be an  $n \times n$  unitary matrix satisfying  $\mathcal{U}^n = \mathbb{1}$ , and let  $|\psi\rangle$  be the seed state. The Gram matrix  $\mathcal{G}^{\mathbb{Z}/n\mathbb{Z}}$  elements associated with the ensemble  $\{\mathcal{U}^i |\psi\rangle\}_{i=0}^{n-1}$  are,

$$\mathcal{G}_{i,j}^{\mathbb{Z}/n\mathbb{Z}} = \sqrt{\eta_i \eta_j} \langle \mathcal{U}^i \psi | \mathcal{U}^j \psi \rangle = \sqrt{\eta_i \eta_j} \langle \psi | \mathcal{U}^{j-i} | \psi \rangle = \sqrt{\eta_i \eta_j} \langle \mathcal{U}^{j-i} \rangle_\psi,$$

where we use the shorthand notation,

$$\langle \mathcal{U}^k \rangle_\psi := \langle \psi | \mathcal{U}^k | \psi \rangle.$$

Using this, the Gram matrix  $\mathcal{G}^{\mathbb{Z}/n\mathbb{Z}}$  can be expressed as a circulant matrix,

$$\mathcal{G}^{\mathbb{Z}/n\mathbb{Z}} = \begin{pmatrix} \eta_1 & \sqrt{\eta_1 \eta_2} \langle \mathcal{U} \rangle_\psi & \sqrt{\eta_1 \eta_3} \langle \mathcal{U}^2 \rangle_\psi & \cdots & \sqrt{\eta_1 \eta_n} \langle \mathcal{U}^{n-1} \rangle_\psi \\ \sqrt{\eta_2 \eta_1} \langle \mathcal{U}^{n-1} \rangle_\psi^* & \eta_2 & \sqrt{\eta_2 \eta_3} \langle \mathcal{U} \rangle_\psi & \cdots & \sqrt{\eta_2 \eta_n} \langle \mathcal{U}^{n-2} \rangle_\psi^* \\ \sqrt{\eta_1 \eta_3} \langle \mathcal{U}^{n-2} \rangle_\psi^* & \sqrt{\eta_2 \eta_3} \langle \mathcal{U}^{n-1} \rangle_\psi^* & \eta_3 & \cdots & \sqrt{\eta_3 \eta_n} \langle \mathcal{U}^{n-3} \rangle_\psi^* \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \sqrt{\eta_1 \eta_n} \langle \mathcal{U} \rangle_\psi & \sqrt{\eta_2 \eta_n} \langle \mathcal{U}^2 \rangle_\psi & \sqrt{\eta_3 \eta_n} \langle \mathcal{U}^3 \rangle_\psi & \cdots & \eta_n \end{pmatrix}.$$

Note that the Gram matrix is Hermitian, as expected, since

$$\langle \mathcal{U}^{-j} \rangle_\psi = \langle \psi | \mathcal{U}^{-j} | \psi \rangle = (\langle \psi | \mathcal{U}^j | \psi \rangle)^* = \langle \mathcal{U}^j \rangle_\psi^*.$$

Additionally, by using the identity  $\mathcal{U}^n = \mathbb{1}$ , we can simplify expressions such as,

$$\langle \mathcal{U}^{-n+i} \rangle_\psi = \langle \psi | \mathcal{U}^{-n+i} | \psi \rangle = \langle \psi | \mathcal{U}^i | \psi \rangle = \langle \mathcal{U}^i \rangle_\psi.$$

---

<sup>8</sup>The relevance of this type of ensembles relies on the fact that for a prime number of states, the possible group generated group ensemble

Thus, we may write,

$$\mathcal{G}^{\mathbb{Z}/n\mathbb{Z}} = \begin{pmatrix} \eta_1 & \sqrt{\eta_1\eta_2} \langle \mathcal{U} \rangle_\psi & \sqrt{\eta_1\eta_3} \langle \mathcal{U}^2 \rangle_\psi & \cdots & \sqrt{\eta_1\eta_n} \langle \mathcal{U} \rangle_\psi^* \\ \sqrt{\eta_2\eta_1} \langle \mathcal{U} \rangle_\psi^* & \eta_2 & \sqrt{\eta_2\eta_3} \langle \mathcal{U} \rangle_\psi & \cdots & \sqrt{\eta_2\eta_n} \langle \mathcal{U} \rangle_\psi^* \\ \sqrt{\eta_1\eta_3} \langle \mathcal{U}^2 \rangle_\psi^* & \sqrt{\eta_2\eta_3} \langle \mathcal{U} \rangle_\psi^* & \eta_3 & \cdots & \sqrt{\eta_3\eta_n} \langle \mathcal{U} \rangle_\psi^* \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \sqrt{\eta_1\eta_n} \langle \mathcal{U} \rangle_\psi & \sqrt{\eta_2\eta_n} \langle \mathcal{U}^2 \rangle_\psi & \sqrt{\eta_3\eta_n} \langle \mathcal{U}^3 \rangle_\psi & \cdots & \eta_n \end{pmatrix}.$$

For instance, the  $\mathbb{Z}/4\mathbb{Z}$  group generated gram matrix with equal prior probabilities is,

$$\mathcal{G}^{\mathbb{Z}/4\mathbb{Z}} = \frac{1}{4} \begin{pmatrix} 1 & c_1 & c_2 & c_1^* \\ c_1^* & 1 & c_1 & c_2 \\ c_2 & c_1^* & 1 & c_1 \\ c_1 & c_2 & c_1^* & 1 \end{pmatrix},$$

where we have denoted  $\langle \mathcal{U}^i \rangle_\psi$  as  $c_i$ . This shows the circulant structure of  $\mathcal{G}$  for an equal prior probability case, where each row is a cyclic permutation of the previous one. In other words, the Gram matrices of  $\mathbb{Z}/n\mathbb{Z}$  group generated ensembles are circulant matrices when taking equal priors probabilities. This structure is particularly useful, as circulant matrices can be diagonalized by the discrete Fourier basis, greatly simplifying many computations [11].

The Fourier basis for an  $n \times n$  circulant matrix consists of the set of vectors  $\{\omega_i\}_{i=1}^n$ , where

$$\omega_i = \frac{1}{\sqrt{n}}(1, \gamma^i, \gamma^{2i}, \dots, \gamma^{i(n-1)})^T,$$

and

$$\gamma = e^{\frac{2\pi i}{n}}.$$

Finally, we denote the cardinality of a finite group  $G$ , i.e. the number of its elements of the group, as  $|G|$ . In scenarios with uniform prior probabilities, this implies,

$$\eta_i = \frac{1}{|G|} \quad \forall i \in \{1, \dots, n\}.$$

## 2.5 PREVIOUS RESULTS

Significant progress has been made in the study of the state exclusion task for group generated ensembles. In particular, the work *Quantum State Exclusion for group generated Ensembles of Pure States*[1] presents exact analytical expressions for the success and error probabilities under both the Minimum Error (ME) and Zero Error (ZE) exclusion protocols. In this section we present this results and comment some key aspects of this results regarding our project, in particular we present the concept of *perfect exclusion region* and we discuss the case of ensembles with a prime number of states.

Let  $\mathcal{G}^G$  denote the Gram matrix of a group generated ensemble  $\left\{\left(\rho_i, \frac{1}{|G|}\right)\right\}_{i=1}^{|G|}$ , where  $G$  is a finite group of size  $|G|$ , and let  $\{\lambda_i\}_{i=1}^{|G|}$  be the set of eigenvalues of  $\mathcal{G}^G$ , the Gram Matrix of the group. Assume the eigenvalues  $\left\{\frac{\lambda_i}{|G|} \mid 1 \leq i \leq n\right\}$  are ordered increasingly,

$$i \leq j \Leftrightarrow \lambda_i \leq \lambda_j, \quad \forall i, j \in \{1, \dots, |G|\},$$

i.e.,  $\frac{\lambda_1}{|G|}$  is the smallest and  $\lambda_{|G|}$  the largest eigenvalue. Notice that since we are in the equal probability scenario, we can factor out a  $\frac{1}{|G|}$  factor from the Gram Matrix and consider the matrix  $|G|\mathcal{G}^G$  instead of  $\mathcal{G}^G$ , i.e. the eigenvalues of this matrix simply are  $\{\lambda_i\}_{i=1}^n$ . This is a standard choice for simplicity, when we dealing with equal prior probabilities.

The exclusion probabilities under the Minimum Error protocol are given by,

$$P_{ME}^s = \min \left\{ 1, 1 - \left( \frac{\sqrt{\lambda_{|G|}} - \sum_{i<|G|} \sqrt{\lambda_i}}{|G|} \right)^2 \right\}.$$

For the Zero Error protocol, the corresponding expressions are,

$$P_{ZE}^s = \min \left\{ 1, 1 - \frac{\sum_{i=1}^{|G|} \sqrt{\lambda_i} \left( \sqrt{\lambda_{|G|}} - \sum_{j<|G|} \sqrt{\lambda_j} \right)}{|G|} \right\}.$$

A key feature of these results is their independence from the specific group generating the ensemble. That is, for any two group generated ensembles  $A$  and  $B$  corresponding to groups  $G_A$  and  $G_B$ , with  $G_A \neq G_B$  but  $|G_A| = |G_B|$ , if their respective Gram matrices  $\mathcal{G}^{G_A}$  and  $\mathcal{G}^{G_B}$  share the same eigenvalues, then the exclusion probabilities for both ME and ZE protocols are identical. This group-independence property is a cornerstone of the present study.

Another important outcome from [1] is the identification of conditions under which perfect exclusion is achievable, i.e., the exclusion can be carried out with zero error. This occurs if the eigenvalues satisfy the inequality,

$$\lambda_{|G|} \leq \left( \sum_{i < |G|} \sqrt{\lambda_i} \right)^2. \quad (1)$$

We refer to the regime satisfying this inequality as the *perfect exclusion zone*. Within this regime, the success probability of the exclusion task reaches one, implying that exclusion can be performed perfectly.

In this project, we will extend this result by showcasing that the perfect exclusion condition Eq. (1) provides a lower bound for the success probability of exclusion even for non-group generated ensembles. Since this bound equals 1, it implies that any ensemble whether or not group generated that satisfies condition Eq. (1) can achieve perfect exclusion. Thus, the perfect exclusion zone is not exclusive to group generated ensembles, but also includes all ensembles that fulfil the given condition.

Furthermore, we might highlight a key aspect of the analytical solutions for the QSE task from ME and ZE protocols. These results depend solely on the eigenvalues of the Gram matrix and are independent of the specific group structure generating the ensemble. Hence, let the Gram matrix of an ensemble decompose as,

$$\mathcal{G} = UDU^\dagger,$$

where  $U$  is a unitary matrix and  $D$  is the diagonal matrix of eigenvalues. We then encounter two possibilities,

- The eigenvalues satisfy Eq. (1), placing the ensemble in the *perfect exclusion* regime.
- The eigenvalues do not satisfy Eq. (1), placing the ensemble in the *non-perfect exclusion* regime.

In the perfect exclusion regime, the existence of a POVM, such that the measurement outcome allows exclusion of a hypothesis without error, is guaranteed.

In the non-perfect exclusion regime, the analytical results for group generated ensembles provide lower bounds on the success probabilities, and upper bounds on the error probabilities for general ensembles.

Consider, for example, the case of an ensemble of 4 quantum states. There are exactly two groups of four elements,  $\mathbb{Z}/4\mathbb{Z}$  and  $\mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z}$ .<sup>9</sup> This implies that there exist two specific unitary matrices,  $U_{\mathbb{Z}/4\mathbb{Z}}$  and  $U_{\mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z}}$  (up to permutation of rows and columns), for which the analytical solution holds exactly.

---

<sup>9</sup>These are the only non-isomorphic groups of order 4.

Since  $U(n)$  is compact, and assuming continuity of the exclusion probabilities with respect to  $U$  under a given matrix norm, for each of these unitary matrices there exist arbitrarily small neighbourhoods  $\mathcal{B}(U_{\mathbb{Z}/4\mathbb{Z}})$  and  $\mathcal{B}(U_{\mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2\mathbb{Z}})$  such that the exclusion probabilities within these neighborhoods approximate the analytical result as closely as desired. However, the existence of multiple such matrices, and intersecting neighbourhoods, can complicate numerical optimization and analysis.

In contrast, it is useful to consider the case where the ensemble contains a prime number  $p$  of states. In this scenario, the situation simplifies considerably, since there exists only one group, up to isomorphism, of order  $p$ , namely  $\mathbb{Z}/p\mathbb{Z}$ .

This result follows immediately from Lagrange's theorem[12]. The theorem guarantees the order of any element in a finite group<sup>10</sup> must divide the order of the group. Since  $p$  is a prime number, the only positive integers dividing  $p$  are either 1 or  $p$  itself. Therefore, the order of any group element must be either 1 or  $p$ . An element of order 1 must be the identity, so every non-identity element in the group must have order  $p$ . This implies that all non-identity elements generate the entire group, i.e., the group is cyclic. As a result, any group of prime order  $p$  is necessarily cyclic and isomorphic to  $\mathbb{Z}/p\mathbb{Z}$ .

Consequently, for an ensemble of  $p$  quantum states, there exists a unique unitary matrix  $U_{\mathbb{Z}/p\mathbb{Z}}$  (up to reordering) that diagonalizes the Gram matrix in such a way that the analytical results are exact.<sup>11</sup>

Ensembles containing a prime number of states are of particular interest, as the analytical result can be guaranteed to be exact for only one specific ensemble. Consequently, when interpreting the results for the case of generic ensembles in the following sections we can ensure the analytical result is exact in only one instance. Moreover, there is no overlap with other Gram matrices for which the result would also hold exactly.

## 2.6 HAAR MEASURE

In this section, we introduce the concept of a measure on a topological space and define the Haar measure. This is one of the key theoretical tools underlying this project, as we use the Haar measure to ensure a uniform sampling of ensembles when generating Gram matrices for general ensembles.

Let  $\Omega$  be a set, and let  $\Sigma$  be a  $\sigma$ -algebra over  $\Omega$ . A measure  $\mu$  on the measurable space  $(\Omega, \Sigma)$  is a set function  $\mu : \Sigma \rightarrow \mathbb{R}$  that satisfies the following properties:

- Positive semidefiniteness, i.e. for any  $\chi \in \Sigma$  we have  $\mu(\chi) \geq 0$ .

---

<sup>10</sup>The order of an element  $\tau$  in a group  $G$  is the smallest positive integer  $m$  such that  $\tau^m = e$ , where  $e$  denotes the identity/neutral element of the group.

<sup>11</sup>Moreover, the columns of this matrix correspond to the elements of the Fourier basis, as discussed in Section 2.4, particularly in the example involving  $\mathbb{Z}/n\mathbb{Z}$ .

- $\mu(\emptyset) = 0$ .
- Sigma additivity, i.e. given a countable set  $\{\chi_i \in \Sigma | i \in \mathbb{N}\}$  of pairwise-disjoint sets<sup>12</sup>  $\mu$  fulfils,

$$\mu\left(\bigsqcup_{i=1}^{\infty} \chi_i\right) = \sum_{i=1}^{\infty} \mu(\chi_i).$$

Now, let  $\Omega$  be a topological group. A Haar measure  $\mu$  on a set  $\Omega$  is a measure defined on the Borel  $\sigma$ -algebra  $\Upsilon$  of  $\Omega$ <sup>13</sup>, satisfying the following properties:

- Invariance under transition, i.e. for any  $\omega \in \Omega$  and  $v \in \Upsilon$  we have  $\mu(\omega v) = \mu(v)$ .
- The measure is finite for any compact Borel subset, i.e. for any  $v \in \Upsilon$  compact we have that  $\mu(v) < \infty$ .
- $\mu$  is outer regular, i.e. for any  $v \in \Upsilon$

$$\mu(v) = \inf_{\vartheta \text{ open}} \{\mu(\vartheta) | v \subseteq \vartheta\}$$

- $\mu$  is inner regular, i.e. for any open  $v \in \Upsilon$ ,

$$\mu(v) = \sup_{\vartheta \text{ compact}} \{\mu(\vartheta) | \vartheta \subseteq v\}$$

It can be shown that the Haar measure is unique up to a constant multiple. In particular, since we are working with the set of unitary matrices,

$$U(n) = \{U \in \mathbb{C}^{n \times n} | U^\dagger U = \mathbf{1}\},$$

which is compact in the usual topology, from the second property we know the Haar measure  $\mu$  on  $U(n)$  to be finite. Therefore, we can normalize it so that  $\mu(U(n)) = 1$ , fully determining the measure. Moreover, since from the first property we know  $\mu$  is invariant under group multiplication, it is uniformly distributed over  $U(n)$ . Hence, this invariance allows us to generate unitary matrices that are randomly and uniformly distributed over  $U(n)$ . This property is one of the cornerstones of our project, as it allows us to convert the uniform distribution of random unitary matrices into a uniform distribution over general ensembles of quantum states.<sup>14</sup>

---

<sup>12</sup>This means that  $\chi_i \cap \chi_j = \emptyset$  for any  $i, j \in \mathbb{N}$  if  $i \neq j$ .

<sup>13</sup>A full definition of Borel sets is beyond the scope of this work, it is enough to say they are sets generated from the open sets of  $\Omega$  through countable unions, intersections, and complements.

<sup>14</sup>We present this conversion in the Methodology section (Section 3).

### 3 METHODOLOGY

All the used code in this project is hosted in the GitHub repository [13], where additional documentation is available detailing the functionality and structure of each script and class involved in the implementation. The numerical analysis is performed by generating ensembles uniformly distributed taking into account all possibilities and then solving the SDP problems presented in Section 2.2.

The core of the numerical analysis is the implementation of a Semi-Definite Programming (SDP) solver based on the MOSEK optimization suite [14], interfaced through the Python-based PICOS optimization library [15].

To analyze both group generated and generic quantum state ensembles, we developed a method for generating random Gram matrices with prescribed spectral properties.

A Numpy Random Number Generator (RNG)[16] produces a set of  $n$  non-negative real numbers  $\{\lambda_i\}_{i=1}^n$  that are normalized to satisfy the trace condition,

$$\sum_{i=1}^n \lambda_i = 1.$$

These values are used as the eigenvalues of the Gram matrix, forming the diagonal matrix  $D = \text{diag}(\lambda_1, \dots, \lambda_n)$ .

Next, we generate a unitary matrix  $U$  and construct the Gram matrix as,

$$\mathcal{G} = UDU^\dagger.$$

At this point, we choose whether the ensemble is to be group generated or generic.

For a generic ensemble, the unitary matrix  $U$  is drawn randomly according to the Haar measure [17], which defines the unique uniform probability measure on the unitary group  $U(n)$  that is invariant under group multiplication. To ensure this uniformity, we use the algorithm introduced by Francesco Mezzadri in [18], which provides an efficient and accurate way of sampling unitary matrices while uniformly covering  $U(n)$ .

This aspect is crucial: if the random generation of unitary matrices did not uniformly cover  $U(n)$ , the numerical analysis would be fundamentally flawed. It would lead to an overrepresentation of certain types of ensembles, potentially missing rare or atypical configurations. As a result, ensembles that might violate the theoretical lower bound could be systematically avoided, rendering the conclusions of the analysis unreliable.

In the case of a group generated ensemble, we restrict ourselves to ensembles generated by the cyclic group  $\mathbb{Z}/n\mathbb{Z}$ . The corresponding unitary matrix  $U$  is constructed such that its columns are the vectors of the discrete Fourier basis, as discussed in Section 2.4 (*group generated Ensemble*).

Other groups are omitted in our analysis since we can always choose  $n$  to be a prime number, in which case the only group of order  $n$  (up to isomorphism) is the cyclic group  $\mathbb{Z}/n\mathbb{Z}$ . This significantly simplifies the group structure and ensures that the only group generated ensemble under consideration corresponds to a well-defined, unique construction.

This methodology provides a flexible yet rigorous foundation for both exploring generic quantum ensembles and benchmarking them against analytically tractable group generated cases.

## 4 RESULTS AND DISCUSSION

The beginning of the analysis consists in showing up the key differences between ME and ZE protocols, and the concordance of the SDP's numerical results with the analytical results given in 2.5.

The case of ensembles conformed by 3 states is one of the main objects of study, that is because it is the only ensemble that we can entirely represent 2 dimensional plots with. In other to show up this fact, let us analyze the case of a  $\mathbb{Z}/3\mathbb{Z}$  ensemble for equal priors probabilities. The Gram matrix in this case takes the form,

$$\mathcal{G}^{\mathbb{Z}/3\mathbb{Z}} = \frac{1}{3} \begin{pmatrix} 1 & c & c^* \\ c^* & 1 & c \\ c & c^* & 1 \end{pmatrix}$$

with  $c \in \mathbb{C}$ . Note that, with respect to previous notation, we write  $c = \langle U \rangle_\psi$ , where  $c$  and  $c^*$  denote the overlap between different states. We can parametrize  $c$  as  $c = |c|e^{i\phi}$ , and since we are analyzing normalized states,

$$|c| \in [0, 1], \quad \phi \in [0, 2\pi]$$

we observe two Degrees of Freedom (DoF).

Since 3 is a prime number, the only group of order 3 is  $\mathbb{Z}/3\mathbb{Z}$ , as discussed in Appendix (D)<sup>15</sup>. The Gram matrix can be diagonalized as,

$$\mathcal{G}^{\mathbb{Z}/3\mathbb{Z}} = U_{\mathbb{Z}/3\mathbb{Z}} D U_{\mathbb{Z}/3\mathbb{Z}}^\dagger,$$

where  $U_{\mathbb{Z}/3\mathbb{Z}}$  is the unitary matrix with Fourier basis vectors as columns. The eigenvalues of the simplified matrix, i.e.  $3\mathcal{G}^{\mathbb{Z}/3\mathbb{Z}}$  matrix are denoted as  $\{\lambda_1, \lambda_2, \lambda_3\}$  with  $\lambda_1 \leq \lambda_2 \leq \lambda_3$ . Since,

$$\sum_{i=1}^3 \lambda_i = 3$$

we again find only two DoFs, consistent with our earlier parameterization. Furthermore, since  $\mathcal{G}^{\mathbb{Z}/3\mathbb{Z}} \geq 0$ , we have,

$$\lambda_i \geq 0 \quad \forall i \in \{1, 2, 3\},$$

---

<sup>15</sup>In dis appendix we discuss the limit case scenarios for general ensembles.

implying the eigenvalues must lie in the interval  $[0, 3]$ .<sup>16</sup> Therefore,

$$\lambda_3 \in [0, 3], \quad \lambda_2 \in [0, \lambda_3], \quad \lambda_1 = 3 - \lambda_2 - \lambda_3.$$

This scenario is particularly interesting as it is the only ensemble with a small enough dimension to fully visualize all parameter dependencies and study the ensemble structure.<sup>17</sup> Higher-dimensional cases are too complex for full representation, while two-state cases reduce to standard quantum state discrimination (QSD) as previously discussed.

#### 4.1 COMPARISON ME VS. ZE

Here we present a comparison between both protocols for ZE and ME giving insights on the protocols's essence and contextualising the problem in a visual way.

In Figure (1) we present the ME (left) and ZE (right) protocols results for the QSE task. In particular Figure (1) shows two heatmaps of the average successful exclusion probability under the Minimum Error (ME) protocol for a  $\mathbb{Z}/3\mathbb{Z}$  group generated ensemble. Probabilities are shown as functions of the modulus  $|c|$  (x-axis) and phase  $\theta$  (y-axis) of the overlap  $c = |c|e^{i\theta}$ , which fully determines the Gram matrix. Notice we take equal prior probabilities, as discussed in the analytical results in Section (2.5).

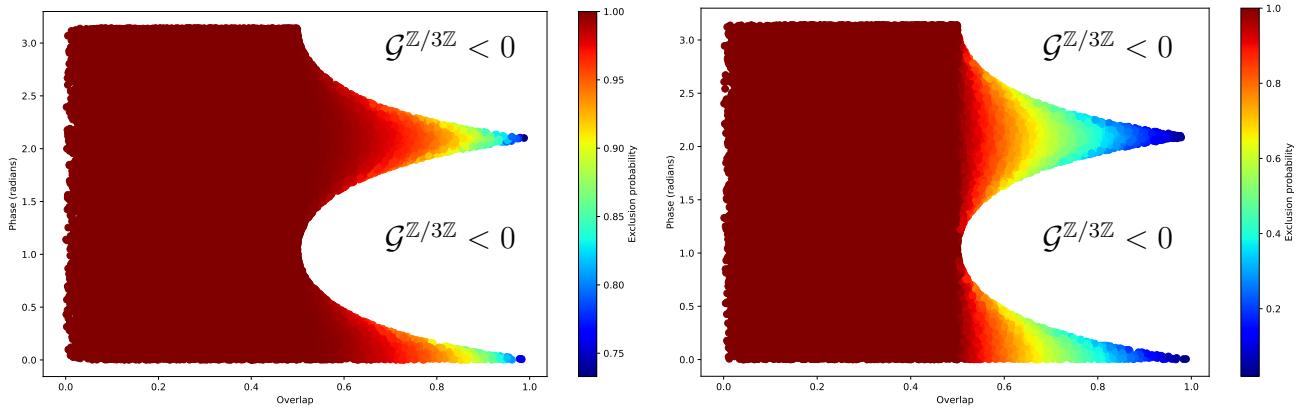

Figure 1: Heatmap of the success probability for Minimum Error (ME) (left) and Zero Error (ZE) (right) quantum state exclusion in a  $\mathbb{Z}/3\mathbb{Z}$  ensemble with equal prior probabilities.

The colorless regions correspond to parameters where  $\mathcal{G}^{\mathbb{Z}/3\mathbb{Z}}$  is not positive semi-definite, and leading up to non-valid Gram matrices, since positive semi-definition is inherent to a Gram matrix.

<sup>16</sup>In general, eigenvalues lie in  $[0, n]$  for an  $n$ -dimensional ensemble, even for non-group generated ensembles.

<sup>17</sup>Visualizations include two parameters along with the success/exclusion probability of the respective protocol.

At this stage, we have developed some intuition behind these results. Consider an ensemble of highly similar quantum states. When the modulus of the overlap between any two states in the ensemble is given by  $|\langle \psi_i | \psi_j \rangle|^2 = |c|$ , and  $|c| \rightarrow 1$ , the states become nearly indistinguishable. In this limiting case, the ensemble effectively consists of identical states.<sup>18</sup>

Since all the states are approximately the same, it becomes impossible to distinguish between them. The best approach we can take is to guess randomly. Consequently, the probability of correctly excluding a state different from the actual (unknown) target state by random guessing is  $\frac{n-1}{n}$ . In this case, when  $n = 3$ , this probability is  $\frac{2}{3}$ . Therefore, in this limit, this is the best achievable performance, and the success probability for the ME exclusion protocol is  $\frac{2}{3}$ .

On the other hand, since the states are indistinguishable, we can never be certain that the excluded state is not the unknown target state. Thus, the probability of successful exclusion in the ZE protocol is 0, i.e. we cannot perform unambiguous exclusion.

A more detailed analytical discussion is provided in Appendix D, where we explore this limiting case by computing the Gram matrix and connecting the analytical results to the intuitive arguments presented here.

Thus, we observe this intuition clearly corresponds to the results from Figure (1). For the limit case scenario of  $|c| = 1$  in the ME protocol we can never do better than taking a random guess, i.e. the probabilities spectrum consists in the interval  $[\frac{2}{3}, 1]$ . Notice this random exclusion procedure only remains valid for the equal prior probabilities case, if we want to extend this idea to a generic ensemble the best approach can take is a random exclusion with different probabilities. In particular if the state  $\rho_i$  has a prior probability of  $\eta_i$  we exclude the state  $\rho_i$  state with a probability of  $\eta_i$ . All in all the final  $P_{ME}^s$  is the same in the equal and non-equal prior probabilities i.e.  $\frac{2}{3}$ .

Still, the ZE success probabilities are always lower than those of the ME protocol. This is explained by the stricter constraints imposed in the ZE scenario. Notice both probabilities are computed in a completely symmetric way,

$$P_{ME}^s \sim P_{ZE}^s \sim 1 - \sum_{i=1}^n \text{Tr}(\Pi_i \rho_i).$$

Nevertheless, in the ZE case we enforce  $\text{Tr}(\Pi_i \rho_i) = 0$  for all the POVM's elements except one<sup>19</sup>. Thus, the system is more constrained in the ZE protocol, then the optimization of the probability cannot be performed up to the same point as in the ME protocol. Hence, the success probabilities for ME are greater than the ones obtained with the ZE protocol.

---

<sup>18</sup>One might argue this ensemble corresponds to a group generated ensemble from the trivial group.

<sup>19</sup>Naturally the POVM element that is not enforced to be orthogonal is the one that yields to an inconclusive result, i.e.  $\Pi_?$ .

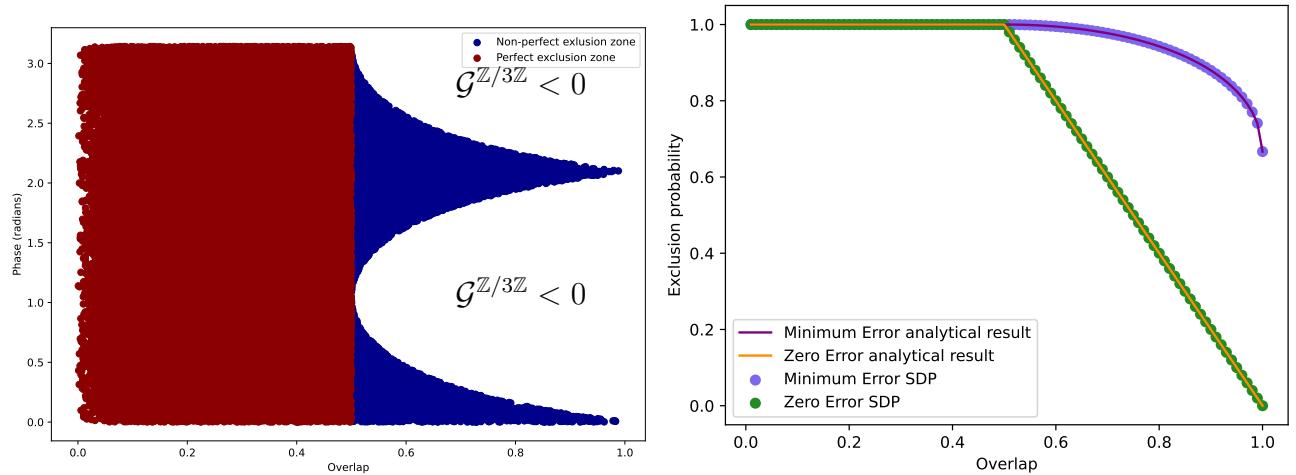

Figure 2: Plot of the successful exclusion probabilities for the SDP results for the ME, ZE protocols in a  $\mathbb{Z}/3\mathbb{Z}$  ensemble imposing phase=0 as well as the results given by the analytical expressions (left). Perfect exclusion zone for a  $\mathbb{Z}/3\mathbb{Z}$  ensemble in terms of the overlap's modulus and phase (right).

Crucially, we observe perfect exclusion is possible even when perfect discrimination is not<sup>20</sup>, in this regime seems to correspond to the ensembles such that the modulus of the overlap between two ensembles do not overtake  $\frac{1}{2}$ . Nevertheless, this description is purely observational, we will give a better description in Section (4.2). In Figure (2) (left) we highlight the regions where perfect exclusion is achieved, i.e. the red zone, even outside the perfect discrimination regime. Notice this regime appears in both protocols ZE and ME.

In Figure (2) (right) we present de dependency on the modulus of the overlap in the  $\mathbb{Z}/3\mathbb{Z}$  group generated ensemble imposing the phase being equal to 0. The result is analogous to Figure (13) but in the exclusion task. The existence of the perfect exclusion zone appears in overlap values between 0 and  $\frac{1}{2}$ .

We highlight the good performance of the ME protocol up to limit values were the result tends to  $\frac{2}{3}$  when the ensemble is made of indistinguishable states (i.e. the same state).

## 4.2 THE PERFECT EXCLUSION REGIME AND GENERAL ENSEMBLES

In this section, we present the results for ensembles generated by the group  $\mathbb{Z}/3\mathbb{Z}$ , analyzed across the spectrum of eigenvalues, i.e. the analogous results from the previous section in the eigenvalues spectrum. We also explicitly show the conditions for perfect exclusion, we give a proper analysis of this regime, and provide an initial exploration of the probabilities excluding successfully for general ensembles being bounded from below by the group generated results of three quantum states.

<sup>20</sup>See Appendix (C) Comparison QSD VS. QSE

Although the *Overlap modulus - phase* spectrum might seem as the most intuitive representation, the spectrum of Gram's matrix eigenvalues results the most appropriate representation for the perfect exclusion zone as well as the discussion and its comparison for general ensembles. Carrying on with the previous discussion, one can check the two DoF now appear as two of the eigenvalues. In the Figure (3) the results for the exclusion task under the ME protocol (left) and ZE protocol (right) for the  $\mathbb{Z}/3\mathbb{Z}$  group generated ensemble are represented. The axis represent two of the eigenvalues of the Gram matrix and a heatmap presents the probability for a perfect exclusion in the given conditions.

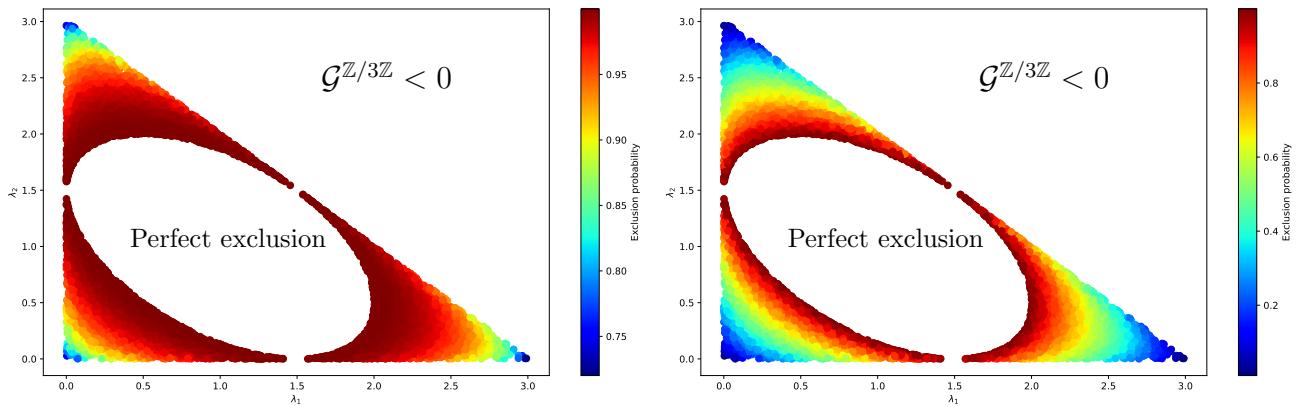

Figure 3: Plot of the success exclusion probability in the eigenvalues spectrum for the ME (left) and ZE (right) protocol for a  $\mathbb{Z}/3\mathbb{Z}$  group generated ensemble.

The order in eigenvalues is obviated in the representation, i.e. we can find conditions such that  $\lambda_i > \lambda_j$  and others conditions such that  $\lambda_i < \lambda_j$  for  $i, j \in \{1, 2, 3\}$

Notice the missing eigenvalue is determined by the other two via,<sup>21</sup>

$$\lambda_3 = 3 - \lambda_1 - \lambda_2.$$

Since the Gram matrix is a positive semidefinite matrix we know that  $\lambda_3 \geq 0$ , the limit case scenario  $\lambda_3 = 0$  defines the line,

$$\lambda_2 = 3 - \lambda_1,$$

that constraints the possible eigenvalues to only reach values under this line. Otherwise the remaining value would be negative leading up to non-valid Gram matrices as discussed in the previos plots. Naturally, we also know  $\lambda_1, \lambda_2 > 0$ , then the region  $\Omega$  where the system leads up

<sup>21</sup>Recall we are factoring out the constant prior probability from the standard Gram Matrix, i.e. the actual eigenvalues from the Gram Matrix defined in Section 2.3 are  $\left\{\frac{\lambda_i}{3}\right\}_{i=1}^n$ .

to consistent Gram matrices is,

$$\Omega = \{(\lambda_1, \lambda_2) \in \mathbb{R}^2 \mid \lambda_1 \geq 0, \lambda_2 \geq 0, \lambda_1 + \lambda_2 \leq 3\}.$$

This region  $\Omega$  is depicted in the Figure (3) as bottom left triangle, where our system is precluded. Inside this region we can find the perfect exclusion zone, i.e. the eigenvalues such that Eq.(1) is fulfilled. In particular, if we set  $\lambda_i$  with  $i \in \{1, 2, 3\}$  to be the greatest eigenvalues and denote  $\lambda_j, \lambda_k$  as the remaining 2 eigenvalues, we know perfect exclusion to be archived if,

$$\sqrt{\lambda_i} \leq \sqrt{\lambda_j} + \sqrt{\lambda_k}.$$

With a little bit of algebra and recalling that  $\lambda_3 = 3 - \lambda_1 - \lambda_2$  we can derive the regime of perfect exclusion denoted as  $\Delta$  comprehends the eigenvalues such that,

$$(\lambda_1, \lambda_2) \in \Delta \Leftrightarrow \lambda_1^2 + 4\lambda_2^2 + 4\lambda_1\lambda_2 - 12\lambda_1 - 12\lambda_2 + 9 \leq 0$$

By plotting the  $\Delta$  region it turns out immediately this region corresponds to the colourless perfect exclusion regime in Figure (3).

Naturally we can prove the perfect exclusion zone to be a subset of valid Gram matrixes i.e.  $\Delta \subset \Omega$ . Then, the non-perfect exclusion regime is the remaining part of the triangle i.e.,

$$\text{Non-perfect exclusion regime} = \Omega \setminus \Delta.$$

The limit case scenarios corresponding to  $\lambda_i = 3$  and  $\lambda_j, \lambda_k = 0$  are located in the vertex of the triangle<sup>22</sup>. Additionally, the cases corresponding to the edges are those with one state repeated 2 times and one different from the other 2. This ensembles can also be understood as a limit case scenario systems.

In practice this scenario is entirely equivalent to a 2 quantum states exclusion (QSE) system. Nevertheless we know this to be equivalent to a 2 quantum states discrimination system (QSD), therefore perfect discrimination/exclusion cannot be archived unless the states are orthogonal. This last case corresponds to the intersection of the ellipse  $\Delta$  with the triangles edges, this can be described as the ensembles with associated Gram matrices whose eigenvalues  $\lambda_i, \lambda_j, \lambda_k$  are,

$$\lambda_i = \lambda_j = \frac{3}{2} \quad \lambda_k = 0.$$

Additionally, we observe that no ensembles yield to lower exclusion success probabilities  $P_{ME}^s$  than  $\frac{2}{3}$  as expected from the discussion in Appendix D.

---

<sup>22</sup>Remember this case correspond to sets with the same state repeated 3 times discussed in Appendix (D)

Regarding the ZE protocol result, i.e. Figure (3) right, we observe the result is consistent with all the previous observations and we can also observe the worst case scenario to tend to a 0 successfull exclusion probability as expected. Also, the probabilities remain with lower values than the ones obtained with the Minimum Error (ME) protocol. Still the perfect exclusion regions are the same.

Hence, we present the result for randomly generated ensembles, i.e. a general ensembles in Figure (4).

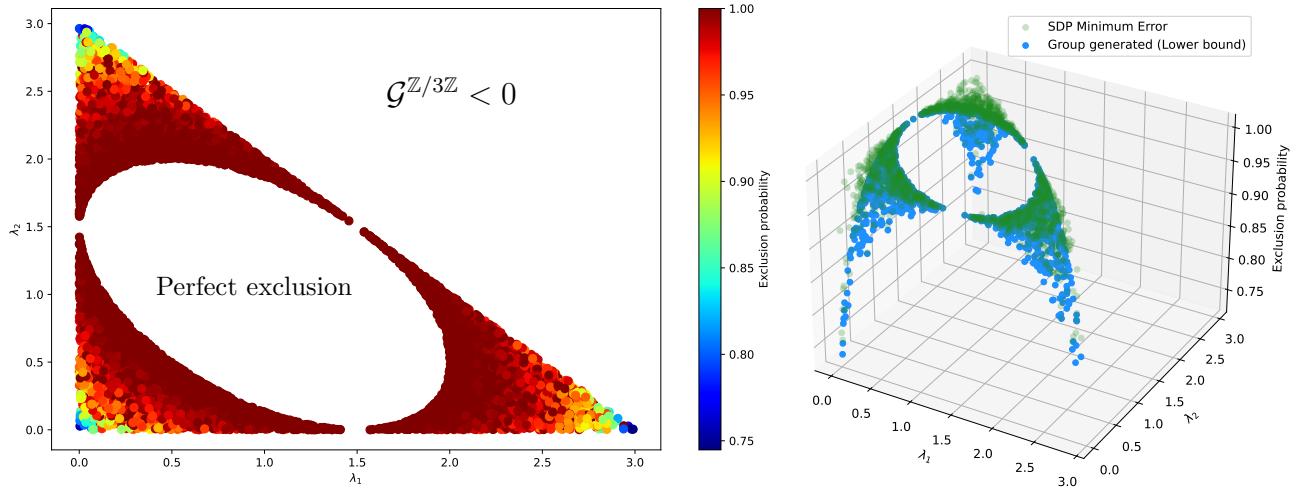

Figure 4: Heat map plot of the success exclusion probability in the eigenvalues spectrum for the ME protocol for generic ensembles (left) and 3D Plot of the success exclusion probability in the eigenvalues spectrum for the ME protocol for a group generated and generic ensembles (right)

A remarkable feature is that each ensemble has been checked to not have a successful exclusion probability that overtakes the value from the  $\mathbb{Z}/3\mathbb{Z}$  group generated ensemble pointing this value to be a lower bound for the general case scenario.

In Figure (4) we present a 3D plot for the comparison of the success probability for exclusion for ensembles of 3 states between generic and group generated ensembles. The  $x$  and  $y$  axis representing the eigenvalues of the Gram matrix are analogous to previous figures. Nevertheless the  $z$  axis shows the success probability for exclusion instead of the previous heat maps. Here we can observe how the randomly generated states raise the probabilities over the group generated values. As we have mentioned in the *Methodology section* (i.e. Section 3), the generation of unitary matrices that fill  $U(n)$  according Haar measure ensures the Gram matrices we are generating comprehend the entire set of possible Gram matrices homogeneously. Furthermore, we observe how the group generated results lay under the results for general ensembles SDPs, i.e. these results are bounded from below by the group generated results.

### 4.3 DISTRIBUTION OF THE GENERAL ENSEMBLES SUCCESS EXCLUSION PROBABILITY

In this section, we present the main results of the project. Specifically, we provide analytical results for generic ensembles and examine how the success probabilities for quantum state exclusion are distributed in relation to the lower bound defined by group generated ensembles.

We begin by recalling that any Gram matrix  $\mathcal{G}$  can be decomposed as  $\mathcal{G} = UDU^\dagger$ , where  $D$  is a diagonal matrix containing the eigenvalues  $\{g_i \geq 0\}_{i=1}^n$ . We fix these eigenvalues such that

$$\sum_{i=1}^n g_i = 1,$$

ensuring they are normalized.<sup>23</sup>

With this eigenvalue spectrum, we compute the analytical lower bound introduced in Section 2.5 and determine whether it falls within the perfect exclusion region. If it does, then any Gram matrix generated as  $\mathcal{G} = UDU^\dagger$  represents an ensemble for which perfect exclusion is feasible, and the lower bound is in fact the success probability, i.e. both are 1. Conversely, if the lower bound lies outside the perfect exclusion region, we explore different unitary matrices  $U$  to generate alternative Gram matrices that share the same eigenvalues, thus preserving the lower bound, while corresponding to distinct ensembles.

We use the algorithm proposed in [18] to generate unitary matrices sampled uniformly from  $U(n)$ . This ensures a comprehensive exploration of the space of possible Gram matrices, i.e., ensembles, corresponding to a fixed lower bound.

It is important to highlight that this method also implicitly generates random prior probabilities for each state, since the diagonal elements of the Gram matrix are the priors probabilities, and generally will differ from one to another. Nevertheless, the analytical lower bound remains valid, as we will show in the following results.

---

<sup>23</sup>Note that this eigenvalue notation differs from that used earlier in the document, where the eigenvalues of the Gram matrix were considered with an overall normalization factor of  $\frac{1}{n}$ , assuming equal prior probabilities and were normalised to  $n$ . To avoid confusion, we change the notation for normalised eigenvalues that sum up to 1 for the general prior probabilities case.

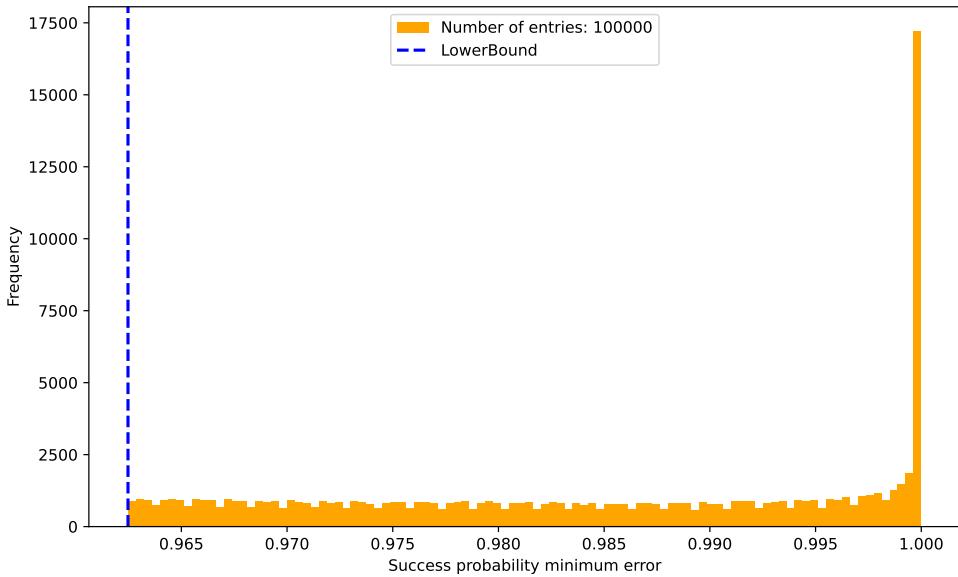

Figure 5: Histogram depicting the distribution of generated Gram Matrices via the success probability for ME protocol with a lower bound of 0.962 for 5 states ensembles of random priors probabilities.

Figure (5) shows the distribution of success probabilities for quantum state exclusion using the ME protocol computed via semidefinite programming (SDP) for 5 states ensembles and random priors probabilities. The histogram's  $x$ -axis represents the exclusion success probability, while the  $y$ -axis indicates the frequency of occurrence across sampled ensembles. Additionally the dashed blue line marks the analytical lower bound.

We emphasize that each computed result has been verified not to fall below this analytical lower bound. Although a few discrepancies were observed, these occurred only at the fifth decimal place, where numerical precision limitations in the SDP solver can affect reliability. These cases are treated as inconclusive due to numerical problems, and no inconsistencies have been found exceeding a deviation in the fourth decimal.

From the results in Figure (5), we observe the ensembles are broadly distributed across a range of success probabilities. However, a significant clustering occurs near a success probability of 1 under the ME protocol, indicating that perfect exclusion is achievable for a substantial subset of these randomly generated ensembles.

These ensembles were generated uniformly by sampling unitary matrices  $U$  from  $U(n)$ , which determine the Gram matrices via the decomposition  $\mathcal{G} = UDU^\dagger$ . Ensembles with Gram matrices structurally similar to those of group generated ensembles, particularly those diagonalized in the

Fourier basis<sup>24</sup>, yield lower success probabilities.

Interestingly, there exists a threshold of deviation from the Fourier basis beyond which all ensembles yield a success probability of 1. In other words, beyond a certain *distance* from the group generated case, i.e. the Fourier basis, the ensembles become sufficiently distinguishable to allow perfect exclusion, regardless of the specific basis in which their Gram matrices are diagonalised.

At this stage we can observe the crucial importance of the generation of the unitary matrices uniformly covering  $U(n)$ , i.e. being generated according to the Haar measure. If we could not ensure we are exploring all the possible ensembles this observations and the study of the generic ensembles case would be completely pointless since we can overrepresent one specific kind of ensembles respect to others.

In Figure (6) we present the analogous results for the ZE protocol for ensembles consisting in 5 states with eigenvalues that lead to an analytical lower bound for success probability of 0.5 in this protocol.

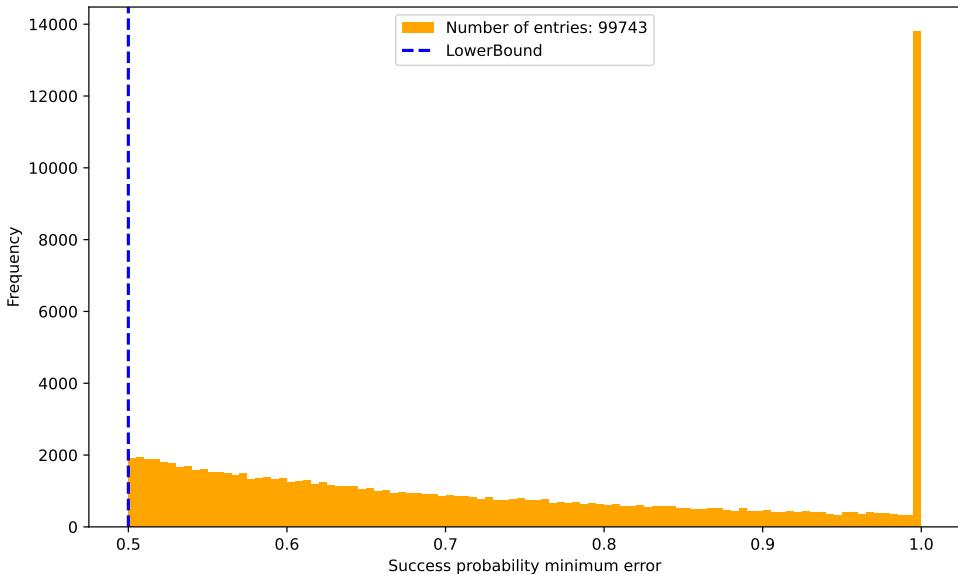

Figure 6: Histogram depicting the distribution of generated Gram Matrices via the success probability for ZE protocol with a lower bound of 0.5 for 5 states ensembles of random priors probabilities.

Thus, we observe a similar behaviour respect to Figure (5), still we attribute the pick of ensembles where perfect exclusion is feasible to the threshold of the *distance* from the group

<sup>24</sup>Recall that we are working with ensembles of a prime number of states, for which the only known analytical result corresponds to the Gram matrix generated by  $\mathbb{Z}/n\mathbb{Z}$ , which is diagonalized in the Fourier basis. A more complete study would consider other group generated cases.

generated case as previously discussed. Still some remarkable aspect of this protocol is the constant is the constant decay in the frequency for higher exclusion probabilities.

As before, no ensemble yields a success exclusion probability below the theoretical lower bound.

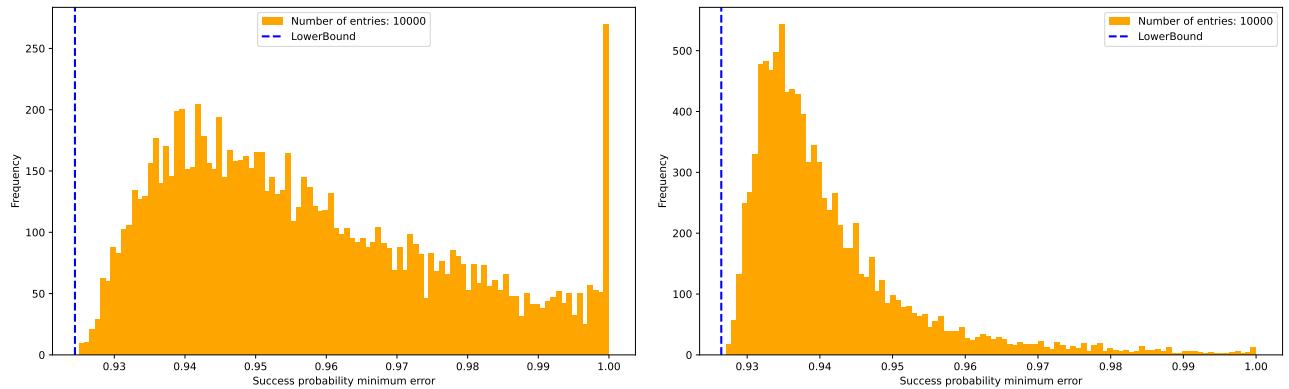

Figure 7: Histogram depicting the distribution of generated Gram Matrices via the success probability for ME protocol with a lower bound of 0.926 for 7 states (left) and 11 states (right) ensembles of random priors probabilities.

In Figure 7, we present the results for the ME protocol applied to ensembles of 7 (left) and 11 (right) quantum states, with a fixed analytical lower bound on the success exclusion probability of 0.926. As the number of states increases, the resulting distributions tend to exhibit a Landau-like shape [19]. For the 7-state ensembles, we continue to observe a significant accumulation near the perfect exclusion region. However, in the case of 11 states, only a small fraction of ensembles achieve perfect exclusion. Furthermore, the main peak of the Landau-like distribution is narrower, and ensembles tend to cluster around this peak rather than at the upper limit.

This behavior can be understood in terms of the relative freedom of success exclusion probabilities. As discussed in Appendix D, any exclusion probability for a generic ensemble of  $n$  states must exceed  $\frac{n-1}{n}$ , the result expected from a random exclusion strategy. Therefore, the exclusion probabilities for 7 and 11 quantum states must lie within the following intervals,

$$\left[ \frac{6}{7}, 1 \right] \sim [0.858, 1] \quad \left[ \frac{10}{11}, 1 \right] \sim [0.909, 1],$$

Although both cases are analyzed with the same lower bound of 0.926, they are not relatively equivalent. For the 7 state case, this lower bound lies approximately at the midpoint of the possible interval, thereby pushing the generation of random ensembles closer to the perfect exclusion. This results in the observable peak of ensembles of success exclusion probability of 1.

<sup>25</sup> In contrast, for the 11 state case, the analytical lower bound is very close to the minimum of the allowed region, meaning ensembles are relatively farther from perfect exclusion, hence, the peak located at 1 does not appear.

We can interpret this phenomenon as the lower bound compressing the region in which exclusion probabilities can appear. For 7 states, the interval is more compressed, forcing a greater amount of ensembles to exhibit high exclusion probabilities, and thus more frequently reach the perfect exclusion, forming a peak.

This compression effect also helps to explain the location of the peak in the Landau-shaped distribution. In the 11 state case, the lower bound is closer to the exclusion probability expected from a random strategy. As a result, the eigenvalues<sup>26</sup> of the corresponding Gram matrices resemble those of an ensemble composed entirely of identical states.<sup>27</sup> Therefore, most Gram matrices correspond to ensembles with very similar states yielding to exclusion probabilities close to the analytical lower bound since this is almost the same as the exact result of ensembles conformed by the same state. In contrast, the eigenvalues for the 7 state case are significantly different from this limit case, leading to more diverse exclusion probabilities and a higher chance of achieving perfect exclusion.

In Figure (8), we present the corresponding results for ensembles composed of 7 (left) and 11 (right) quantum states under the ZE protocol.

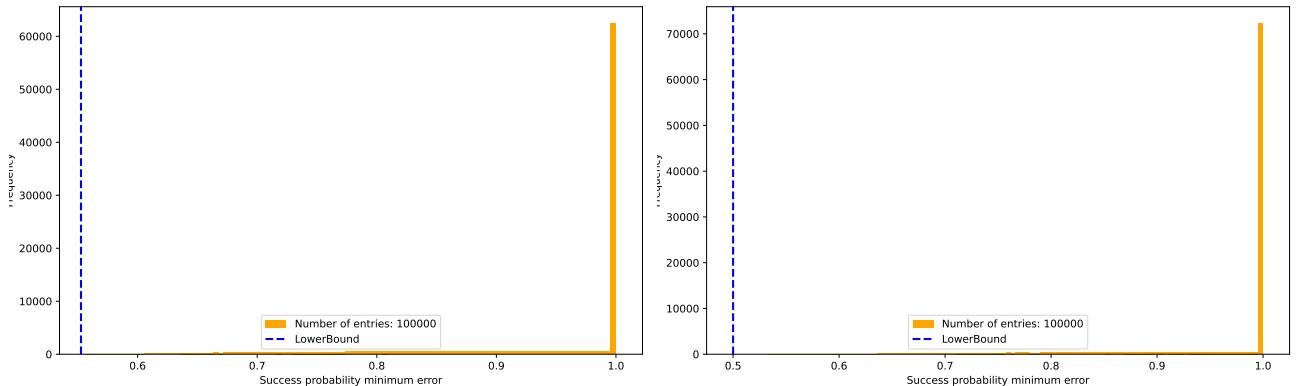

Figure 8: Histogram depicting the distribution of generated Gram Matrices via the success probability for ZE protocol with a lower bound of 0.553 for 7 states (left) and 11 states (right) ensembles of random priors probabilities.

<sup>25</sup>Notice that when we refer to *perfect exclusion* there is no direct connection to the *perfect exclusion regime* provided in Eq. (1). In this regime of eigenvalues all the Gram Matrices give rise to ensembles where perfect exclusion can be performed. Now we are outside this regime, i.e. the lower analytical bound is different from 1, but still we can find ensembles where perfect exclusion can be accomplished.

<sup>26</sup>Note that all ensembles in Figure 7 share the same eigenvalues to ensure consistency with the analytical lower bound.

<sup>27</sup>This corresponds to the limit case scenario described in Appendix D, where the Gram matrix has one non-zero eigenvalue and all others equal to zero.

As depicted in Figure (8), the compression effect, previously observed in the ME protocol, is even more pronounced in the ZE setting. Here, the majority of ensembles yield a success exclusion probability of 1, leading to a broad peak at the upper end of the distribution. Notably, this effect appears equally strong in both the 7 and 11 state cases.

As shown in Appendix D, the lower bound on the success exclusion probability for the ZE protocol, when using a random exclusion strategy, is always 0, regardless of the number of states in the ensemble. That is, in the limit case of an ensemble composed entirely of identical states, perfect exclusion becomes impossible, and the probability drops to zero. Consequently, success probabilities under the ZE protocol must lie within the full interval  $[0, 1]$  for any ensemble size, i.e. the usual interval.

Therefore, unlike in the ME protocol, the compression effect induced by the analytical lower bound in the ZE scenario applies equally across all ensemble sizes since this are equally compressed. This explains why the distributions in both the 7 and 11 state cases are similarly skewed toward ensembles where perfect exclusion can be accomplished.

One might perceive an apparent inconsistency with the previous discussion, where we claimed that success probabilities under the ZE protocol to be higher than those obtained with the ME protocol. This discrepancy arises because the eigenvalues of the Gram matrices used in the ZE analysis differ from those in Figure (7), which pertain to the ME protocol. In the ZE setting, the eigenvalues have been shifted in such a way that the ensembles are more likely to achieve perfect exclusion. As a result, most ensembles cluster around a success exclusion probability of 1 and no inconsistency raises up.

#### 4.4 INTUITION BEHIND THE RESULTS

The intuition behind the exclusion task for group generated ensembles being the worst case scenario for this task, thus yielding a lower bound for the probability of excluding a hypothesis state in the general case is as follows. Consider an ensemble  $\{|\psi_i\rangle\}_{i=1}^n$  with a certain degree of symmetry, and a state  $|\psi_j\rangle$  known to be a member of this ensemble. Our goal is to perform the exclusion task, i.e., to identify a state  $|\psi_k\rangle \in \{|\psi_i\rangle\}_{i=1}^n$  such that we *believe*  $|\psi_k\rangle \neq |\psi_j\rangle$ <sup>28</sup>.

Due to the symmetric nature of the ensemble, the states are very similar to each other. This makes it especially difficult to identify which state is different from the unknown state. In contrast, if the ensemble includes a state  $|\tilde{\psi}\rangle$  that is very different from the others, it becomes easier to determine whether  $|\tilde{\psi}\rangle$  matches the unknown state or not. Thus, when the symmetry is broken, exclusion can be performed more accurately.

---

<sup>28</sup>We emphasize the word *believe* because in many scenarios we are not certain about  $|\psi_k\rangle \neq |\psi_j\rangle$ , which corresponds to the *non-perfect exclusion* case.

To illustrate this more concretely, consider the following ensemble involving qubit states,

$$\{|\uparrow\rangle, |\uparrow\rangle, |\uparrow\rangle\}. \quad (2)$$

These are represented on a Bloch circle<sup>29</sup> in Figure (9).

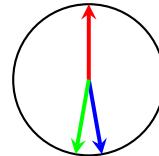

Figure 9: Representation of the ensemble states as projections on the Bloch circle.

It is evident that  $|\uparrow\rangle$  is noticeably different from the other two states. The red arrow points in the opposite direction to the blue and green arrows. Therefore, given an unknown state  $|\uparrow\rangle$  from this ensemble, it is relatively easy to determine whether  $|\uparrow\rangle = |\uparrow\rangle$  or  $|\uparrow\rangle \neq |\uparrow\rangle$ . If  $|\uparrow\rangle = |\uparrow\rangle$ , we can exclude either  $|\uparrow\rangle$  or  $|\uparrow\rangle$ , otherwise, we can exclude  $|\uparrow\rangle$ . In both cases, the exclusion is straightforward.

This is closely related to the task of quantum state discrimination (QSD). If  $|\uparrow\rangle = |\uparrow\rangle$ , the exclusion and discrimination tasks are practically equivalent. However, if  $|\uparrow\rangle \neq |\uparrow\rangle$ , it becomes very difficult to determine whether  $|\uparrow\rangle = |\uparrow\rangle$  or  $|\uparrow\rangle = |\uparrow\rangle$ , as these states are almost indistinguishable. Thus, in this ensemble, the exclusion task may be more feasible than discrimination, showcasing its strength in certain scenarios.

For a more analytical result, and regarding previous results in section (4.2), the success probability of this ensemble would be represented as a dot close to an edge of the triangle of Figure (4).

Now contrast this with a symmetric ensemble, as shown in Figure (10).

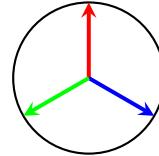

Figure 10: Symmetric ensemble represented on the Bloch circle.

This configuration exhibits perfect symmetry. Define a unitary operator  $\mathcal{U}$  such that,

$$\mathcal{U}|\uparrow\rangle = |\uparrow\rangle,$$

---

<sup>29</sup>The Bloch circle is a projection of the Bloch sphere onto a plane.

then by symmetry,

$$\mathcal{U} |\uparrow\rangle = |\uparrow\rangle, \quad \mathcal{U} |\uparrow\rangle = |\uparrow\rangle.$$

Hence,

$$\mathcal{U}^3 = \mathbb{1}|_{\text{Bloch circle}},$$

where  $\mathbb{1}|_{\text{Bloch circle}}$  denotes the identity operator restricted to this subspace. This implies the ensemble is generated by a cyclic group of order 3, i.e.,  $\mathbb{Z}/3\mathbb{Z}$ .

In such a group generated ensemble, distinguishing any pair of states is equally difficult due to symmetry. Therefore, exclusion becomes more challenging, representing a worst-case scenario compared to the asymmetric case.

## 5 CONCLUSIONS

We have presented a robust protocol for generating ensembles of quantum states, along with their corresponding prior probabilities, in a manner that uniformly samples the full space of possible ensembles<sup>30</sup>. This approach ensures a comprehensive and unbiased exploration for the study of Quantum State Exclusion (QSE). Using this ensemble generation method, we have computed the corresponding Semidefinite Programming (SDP) optimization problems, allowing us to numerically verify and support the analytical results obtained for the success and error probabilities associated with group generated ensembles.

The analytical results, presented in Section 2.5 *Previous Results*, for the success probability in Quantum State Exclusion (QSE) for the Minimum Error (ME) and Zero Error (ZE) protocols for equal prior probabilities for group generated ensambles have provide lower bounds for the success probability in Quantum State Exclusion (QSE) for the same protocols. Our numerical simulations confirm that these group generated ensembles consistently achieve the lowest exclusion success probabilities, thus validating their role as theoretical lower bounds when compared to the broader set of randomly generated ensembles. We have also offered conceptual insights into the intuition of why these bounds persist in the general case, including a geometric interpretation based on Gram matrix structure and ensemble distinguishability.

In addition, we have explored in detail the specific case of the cyclic group  $\mathbb{Z}/3\mathbb{Z}$ , the only group generated ensemble that can be faithfully represented in two dimensions. This visualization not only has provided intuition but also demonstrates the practical advantage of QSE over its counterpart, Quantum State Discrimination (QSD). These results strengthen the case for employing QSE in quantum information tasks where conventional discrimination strategies fall short.

The observations made in this project open the door to further analytical and numerical investigations. Extending this analysis to more generic ensembles, that may reveal new structural properties and exclusion capabilities. Furthermore, from the results and discussions in this project it results obvious that research in hybrid protocols that interpolate between Minimum Error (ME) and Zero Error (ZE) protocols as well as QSE and QSD could potentially yield more optimal performance in practical applications.

In summary, this work contributes both rigorous numerical evidence and conceptual motivation for viewing group generated ensembles as the worst case scenario in the study of quantum state exclusion, i.e. leading up to a lower bound in the exclusion probability. It also highlights promising directions for future work, including the development of tighter bounds, hybrid exclusion strategies, and generalizations of the analitical results.

---

<sup>30</sup>The protocol is presented in the *Methodology* section (Section 3).

## **ACKNOWLEDGEMENTS**

I am grateful to Dr. Ramón Muñoz Tapia for allowing me to be one of his pupils and for presenting this project. I am also deeply grateful to PhD. student Santiago Llorens Fernández for being the lighthouse that illuminates my path throughout this journey.

I would like to acknowledge my mother and sister for their unconditional support, and my father for the values he taught me. Additionally, I would like to thank my friends Francisco Montaño, David Muñoz and Manel Martin for listening to my monologues about my excitement for Quantum State Exclusion.

## A DUAL FORMULATION OF THE PROBLEM

It is often useful to consider the *dual* version of a SDP problem, as it provides both conceptual insights and practical advantages for verifying optimality.

Consider the ensemble  $\{(\rho_i, \frac{1}{n})\}_{i=1}^n$ , where each state  $\rho_i$  appears with uniform prior probability  $1/n$ . The dual SDP corresponding to the Minimum Error (ME) exclusion protocol, when expressed in terms of the error probability, is given by,

$$\begin{aligned}\tilde{P}_{ME}^e &= \max_{\Gamma} \quad \text{Tr } \Gamma \\ \text{subject to} \quad &\frac{\rho_i}{n} - \Gamma \geq 0 \quad \forall i \in \{1, \dots, n\}, \\ &\Gamma^\dagger = \Gamma,\end{aligned}$$

where  $\tilde{P}$  denotes the dual version of the problem.

Similarly, the dual SDP for the success probability in the same protocol reads,

$$\begin{aligned}\tilde{P}_{ME}^s &= \min_{\Gamma} \quad 1 - \text{Tr } \Gamma \\ \text{subject to} \quad &\frac{\rho_i}{n} - \Gamma \geq 0 \quad \forall i \in \{1, \dots, n\}, \\ &\Gamma^\dagger = \Gamma.\end{aligned}$$

For the ZE protocol the dual version of the SDP for the error probability is,

$$\begin{aligned}\tilde{P}_{ZE}^s &= \max_{X \geq 0} \quad 1 - \text{Tr } X \\ \text{subject to} \quad &\sum_{g \in \mathcal{G}} U_g X U_g^\dagger + \nu |\psi\rangle \langle \psi| - \Omega \geq 0 \quad \nu \in \mathbb{R}.\end{aligned}$$

Hence the success probability is,

$$\begin{aligned}\tilde{P}_{ZE}^s &= \min_{X \geq 0} \quad \text{Tr } X \\ \text{subject to} \quad &\sum_{g \in \mathcal{G}} U_g X U_g^\dagger + \nu |\psi\rangle \langle \psi| - \Omega \geq 0 \quad \nu \in \mathbb{R}.\end{aligned}$$

One of the primary uses of the dual formulation is in establishing optimality. If a POVM ansatz yields equal objective values for both the primal and dual problems, i.e.,  $P = \tilde{P}$ , then strong duality holds and the measurement is guaranteed to be optimal.

This duality principle not only provides a tool for verification but also suggests constructive approaches to discovering optimal measurements, especially in structured ensembles such as those generated by group actions.

## B COMPUTATION OF GRAM MATRICES FOR A GROUP GENERATED ENSEMBLES

We can compute the Gram matrix for any group generated ensemble by using the Cayley table [20], also known as the *multiplication table*, of the group. For example, consider the smallest non-commutative group,  $S_3$ , consisting of the symmetries and rotations of an equilateral triangle. Denoting the identity as  $e$ , the rotations elements as  $s$ ,  $s^2$  (one being the result of 2 times the other) and the symmetries  $p$ ,  $q$ , and  $r$ , the Cayley table is,

Table 1: Cayley table of the  $S_3$  group.

$S_3$	$e$	$s$	$s^2$	$p$	$q$	$r$
$e$	$e$	$s$	$s^2$	$p$	$q$	$r$
$s^2$	$s^2$	$e$	$s$	$r$	$p$	$q$
$s$	$s$	$s^2$	$e$	$q$	$r$	$p$
$p$	$p$	$r$	$q$	$e$	$s^2$	$s$
$q$	$q$	$p$	$r$	$s$	$e$	$s^2$
$r$	$r$	$q$	$p$	$s^2$	$s$	$e$

We now identify  $S_3$  as a group of unitary matrices<sup>31</sup>. It follows that the Gram matrix of the  $S_3$  group generated ensemble is the matrix of expected values of the Cayley table entries with respect to the seed state  $|\psi\rangle$ . That is,

$$\mathcal{G}_\psi^{S_3} = \frac{1}{6} \begin{pmatrix} 1 & \langle s \rangle_\psi & \langle s^2 \rangle_\psi & \langle p \rangle_\psi & \langle q \rangle_\psi & \langle r \rangle_\psi \\ \langle s^2 \rangle_\psi & 1 & \langle s \rangle_\psi & \langle r \rangle_\psi & \langle p \rangle_\psi & \langle q \rangle_\psi \\ \langle s \rangle_\psi & \langle s^2 \rangle_\psi & 1 & \langle q \rangle_\psi & \langle r \rangle_\psi & \langle p \rangle_\psi \\ \langle p \rangle_\psi & \langle r \rangle_\psi & \langle q \rangle_\psi & 1 & \langle s^2 \rangle_\psi & \langle s \rangle_\psi \\ \langle q \rangle_\psi & \langle p \rangle_\psi & \langle r \rangle_\psi & \langle s \rangle_\psi & 1 & \langle s^2 \rangle_\psi \\ \langle r \rangle_\psi & \langle q \rangle_\psi & \langle p \rangle_\psi & \langle s^2 \rangle_\psi & \langle s \rangle_\psi & 1 \end{pmatrix}.$$

Notice we have assumed equal prior probabilities, i.e.  $\eta_i = \eta_j = \frac{1}{6}$ . In the non-equal prior probabilities regime we only need to multiply each element for  $\sqrt{\eta_i \eta_j}$  instead of  $\frac{1}{6}$ . Additionally, note that  $\langle e \rangle_\psi = 1$  since  $e = \mathbb{1}$ . Moreover, since  $\mathcal{G}^{S_3}$  is Hermitian, we conclude,

$$\langle p \rangle_\psi, \langle q \rangle_\psi, \langle r \rangle_\psi \in \mathbb{R}, \quad \forall |\psi\rangle \in \mathcal{H},$$

which implies the unitary matrices corresponding to the triangle symmetries  $p$ ,  $q$ , and  $r$  are Hermitian. As a matter of fact we know the eigenvalues of this matrices can only be  $\pm 1$  and at

<sup>31</sup>We treat each group element as a unitary matrix, and the group operation as matrix multiplication.

least one of them must be  $-1$ .<sup>32</sup> This procedure generalizes to any finite group  $G$ , showing that computing the Cayley table is equivalent to computing the Gram matrix of the corresponding group generated ensemble.

## C COMPARISON QSD VS. QSE

Here we present the results for the Quantum State Discrimination (QSD) task to motivate the problem and highlight contrasts with the Quantum State Exclusion (QSE) task, which is the focus of this study.

In Figure (11) we present the ME (left) and ZE (right) protocols results for the QSD task. Recalling the probabilities are shown as functions of the modulus  $|c|$  ( $x$ -axis) and phase  $\theta$  ( $y$ -axis) of the overlap  $c = |c|e^{i\theta}$ , which fully determines the Gram matrix. Notice we take equal prior probabilities, as discussed in the analytical results in Section (2.5). This result is the analogous of Figure (1) for QSD.

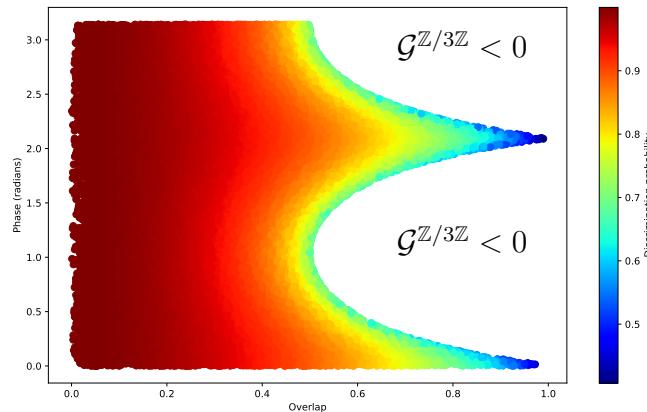

Figure 11: Heatmap of the success probability for minimum error (ME) quantum state discrimination for a  $\mathbb{Z}/3\mathbb{Z}$  group generated ensemble.

In these conditions, the Square Root Measurement (SRM)<sup>33</sup> is optimal, i.e. the result of the SDP matches the one obtained from the SDP in ME protocol. In particular, the SRM is obtained from the square root decomposition of the Gram matrix,

$$\mathcal{G} = S^\dagger S = S^2$$

and is the standard in QSD under the ME protocol [7]. From section (2.3) we know the

---

<sup>32</sup>Otherwise, they would be the identity and we know them to be different by construction.

<sup>33</sup>Also known as the Pretty Good Measurement.

success probability for a successful discrimination with SRM reeds,

$$P_{SRM}^s = \frac{1}{n} \sum_{i=0}^n S_{i,i}^2$$

were  $S_{i,i}$  denotes the diagonal elements of  $S$  and  $n$  the number of quantum states<sup>34</sup>.

As expected, no ensemble yields a success probability below  $1/3$ , consistent with the discussion in Appendix (D). Moreover, as the modulus of the overlap approaches zero, the success probability approaches one, corresponding to orthogonal states, again matching expectations.

Figure (12) shows analogous results for the Zero Error (ZE) protocol under the same conditions.

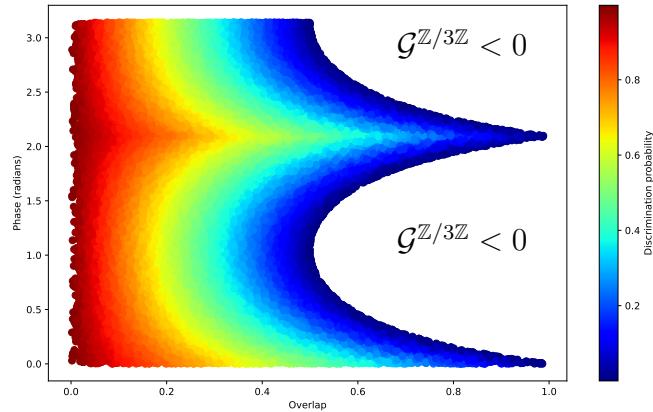

Figure 12: Heatmap of the success probability for zero-error (ZE) quantum state discrimination for a  $\mathbb{Z}/3\mathbb{Z}$  group generated ensemble.

Again, the ZE protocol yields lower probabilities due to its constraints and the limit case scenarios match with the previous discussion in Appendix (D) and Section (4).

Figure (13) compares the performance of the ME, ZE, and SRM protocols.

---

<sup>34</sup>In this case we are taking  $n = 3$ .

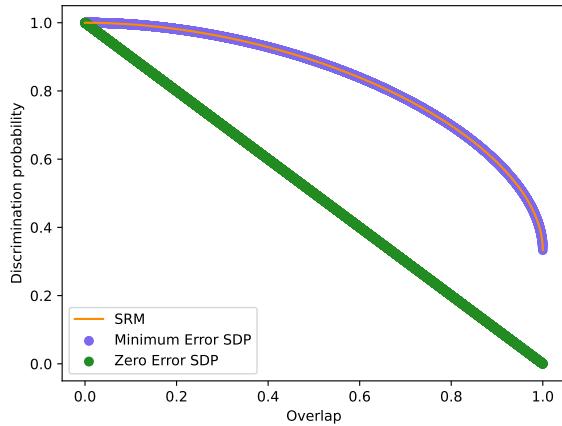

Figure 13: Comparison of successful discrimination probabilities for ME, ZE, and SRM protocols in a  $\mathbb{Z}/3\mathbb{Z}$  ensemble imposing phase=0.

As expected, perfect discrimination is only achieved when the overlap is zero (orthogonal states), and the SRM success probability matches the one obtained from the numerical SDP.

Moreover, we observe the results in QSE are substantially better, the exclusion can be performed with higher precision than the discrimination. This observation is expected. Let us suppose we perform a correct guess in the discrimination of our unknown state, then if we know to which state is correlated our unknown state, we know which states is not correlated to, in other words

$$\text{correct discrimination} \Rightarrow \text{correct exclusion}.$$

However, let us suppose we perform a correct guess in the exclusion task, still we are ignoring which is our unknown state, then,

$$\text{correct exclusion} \not\Rightarrow \text{correct discrimination}.$$

Hence, achieving a correct outcome in the discrimination task implies a correct outcome in the exclusion task but the reciprocal is untrue. This trivial discussion explains the differences in the results and reinforces the potential of QSE.

This highlights the motivation behind the study of QSE, which allows for perfect exclusion in cases where discrimination is impossible. The possibility perfect exclusion for QSE is a major motivation for its study. For example, in a regime where perfect exclusion is possible, having access to multiple copies of an unknown state enables hybrid exclusion-discrimination protocols that can outperform purely discriminative strategies. Even partial information, such as the exclusion of a single quantum state, has value in certain quantum information theories. These features make QSE a fertile ground for further theoretical and applied research.

## D LIMIT CASE SCENARIOS

Let us study the Gram matrix of a limit ensemble composed of  $n$  identical quantum states with equal probabilities, i.e. the same state is repeated  $n$  times in the ensemble with the same probability.<sup>35</sup> The Gram matrix reads,

$$\mathcal{G}^{\text{limit}} = \frac{1}{n} \begin{pmatrix} 1 & 1 & \cdots & 1 \\ 1 & 1 & \cdots & 1 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 1 & \cdots & 1 \end{pmatrix}.$$

The eigenvalues of this matrix are:

$$\begin{aligned} \lambda_n &= 1, \\ \lambda_{n-1} &= 0, \\ &\vdots \\ \lambda_1 &= 0. \end{aligned}$$

Clearly, this set of eigenvalues does not satisfy Eq. (1), i.e., we are in the non-perfect exclusion regime. In fact, we can interpret this ensemble as a group generated ensemble from the *trivial group*,<sup>36</sup> which generates no variation.

Thus, the success and error probabilities for both the ME protocol is,

$$\begin{aligned} P_{ME}^e &= \frac{1}{n}, \\ P_{ME}^s &= \frac{n-1}{n}. \end{aligned}$$

The intuition behind this result is clear. If there is no physical way to distinguish between states, the exclusion must be made randomly, with uniform probability. This observation also extends naturally to QSD.

Since this is a limiting case scenario, the success probability for QSE must be strictly greater than  $\frac{n-1}{n}$  (i.e., the error probability must be less than  $\frac{1}{n}$ ) and for QSD the success probabilities must be strictly greater than  $\frac{1}{n}$  (i.e., the error probability must be less than  $\frac{n-1}{n}$ ).<sup>37</sup> Notice this result holds only for the ME protocol. Otherwise, since the exclusion cannot be accomplished

---

<sup>35</sup>This case may appear paradoxical, since there is no way to distinguish between identical states. Nevertheless, we present it as a limiting scenario.

<sup>36</sup>The trivial group is the group consisting solely of the neutral/identity element.

<sup>37</sup>In this case scenario the discrimination task is the counterpart of the exclusion task.

without ambiguity, the successfull exclusion probability for the ZE protocol is 0 for either QSE or QSD (i.e., the error exclusion probability is 1),

$$\begin{aligned} P_{ZE}^e &= 1, \\ P_{ZE}^s &= 0. \end{aligned}$$

The opposite limiting case is an ensemble of  $n$  orthogonal quantum states  $\{\rho_i\}_{i=1}^n$ . In this case, the Gram matrix becomes the identity,

$$\mathcal{G} = \mathbb{1}.$$

Under these conditions, both QSE and QSD are trivial, as the states form an orthonormal basis. In particular, in the space spanned by these states, we have,

$$\sum_{i=1}^n \rho_i = \mathbb{1},$$

which means that the set  $\{\rho_i\}$  is itself a POVM. The measurement corresponding to this POVM allows perfect identification, or exclusion, hence both QSE and QSD can be performed without error.
